

# Load Balancing and Termination Detection

*Load balancing* – used to distribute computations fairly across processors in order to obtain the highest possible execution speed.

*Termination detection* – detecting when a computation has been completed. More difficult when the computation is distributed.

# Load balancing

(a) Imperfect load balancing leading to increased execution time

(b) Perfect load balancing

# Static Load Balancing

Before execution of any process.

Some potential static load balancing techniques:

- *Round robin algorithm* — passes out tasks in sequential order of processes coming back to the first when all processes have been given a task
- *Randomized algorithms* — selects processes at random to take tasks
- *Recursive bisection* — recursively divides the problem into sub-problems of equal computational effort while minimizing message passing
- *Simulated annealing* — an optimization technique
- *Genetic algorithm* — another optimization technique

Several **fundamental flaws** with static load balancing even if a mathematical solution exists:

- Very difficult to estimate accurately execution times of various parts of a program without actually executing the parts.
- Communication delays that vary under different Circumstances
- Some problems have an indeterminate number of steps to reach their solution.

# Dynamic Load Balancing

Vary load during the execution of the processes.

All previous factors taken into account by making division of load dependent upon execution of the parts as they are being executed.

Does incur an additional overhead during execution, but it is much more effective than static load balancing

# Processes and Processors

Computation divided into *work* or *tasks*.

Processes perform these tasks.

Processes are mapped onto processors.

Since our objective is to keep processors busy, we are interested in the activity of the processors.

Often map a single process onto each processor, so terms *process* and *processor* somewhat interchangeably.

# Dynamic Load Balancing

Can be classified as:

- Centralized
- Decentralized

# Centralized dynamic load balancing

Tasks handed out from a centralized location.  
Master-slave structure.

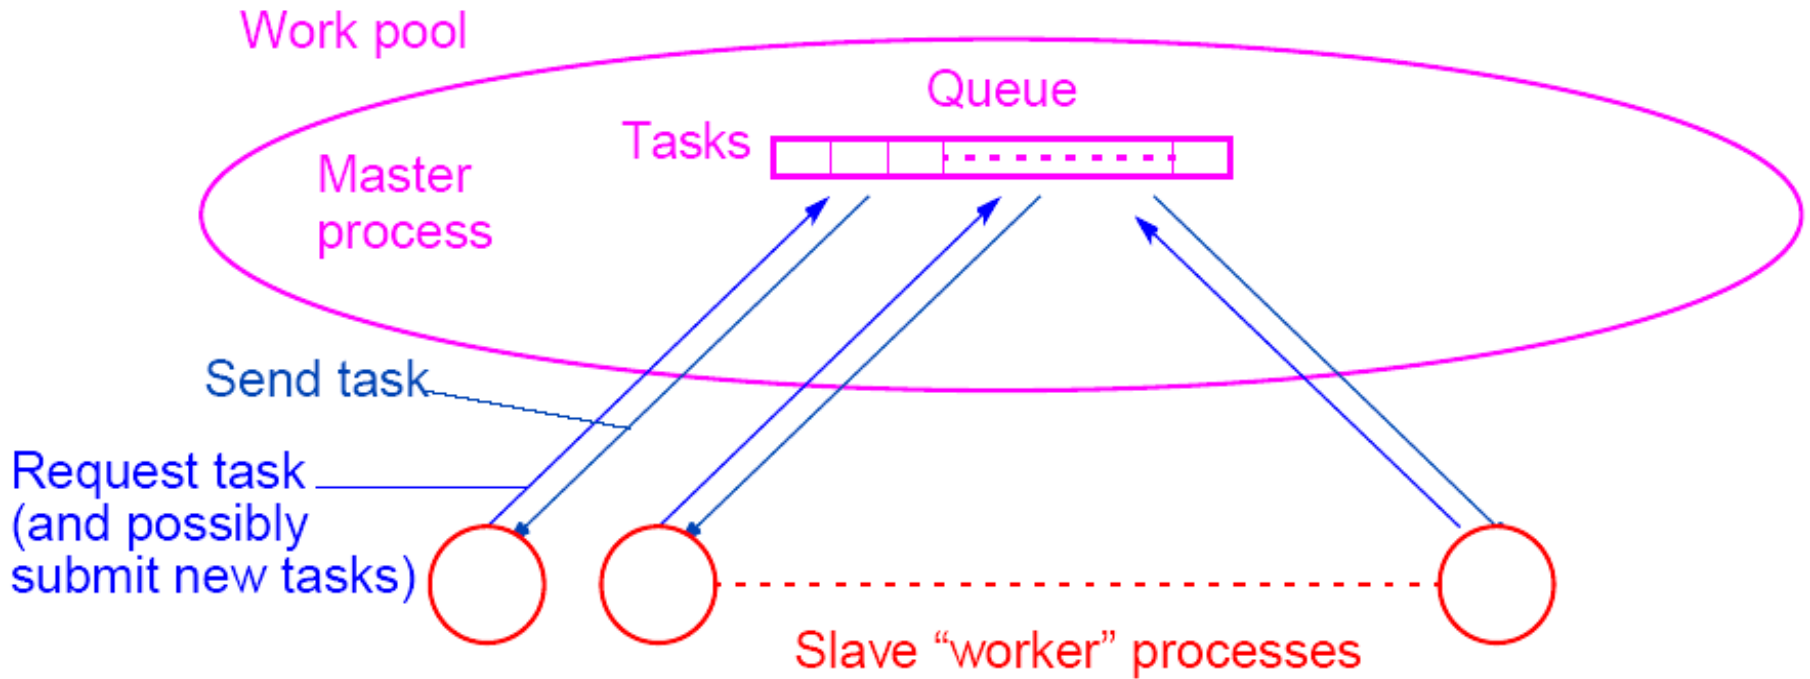

# Centralized Dynamic Load Balancing

Master process(or) holds collection of tasks to be performed.

Tasks sent to slave processes. When a slave process completes one task, it requests another task from the master process.

Terms used : *work pool, replicated worker, processor farm.*

# Centralized work pool

# Decentralized dynamic load balancing

Tasks are passed between arbitrary processes.

Collection of worker processes operate upon the problem and interact among themselves, finally reporting to a single process.

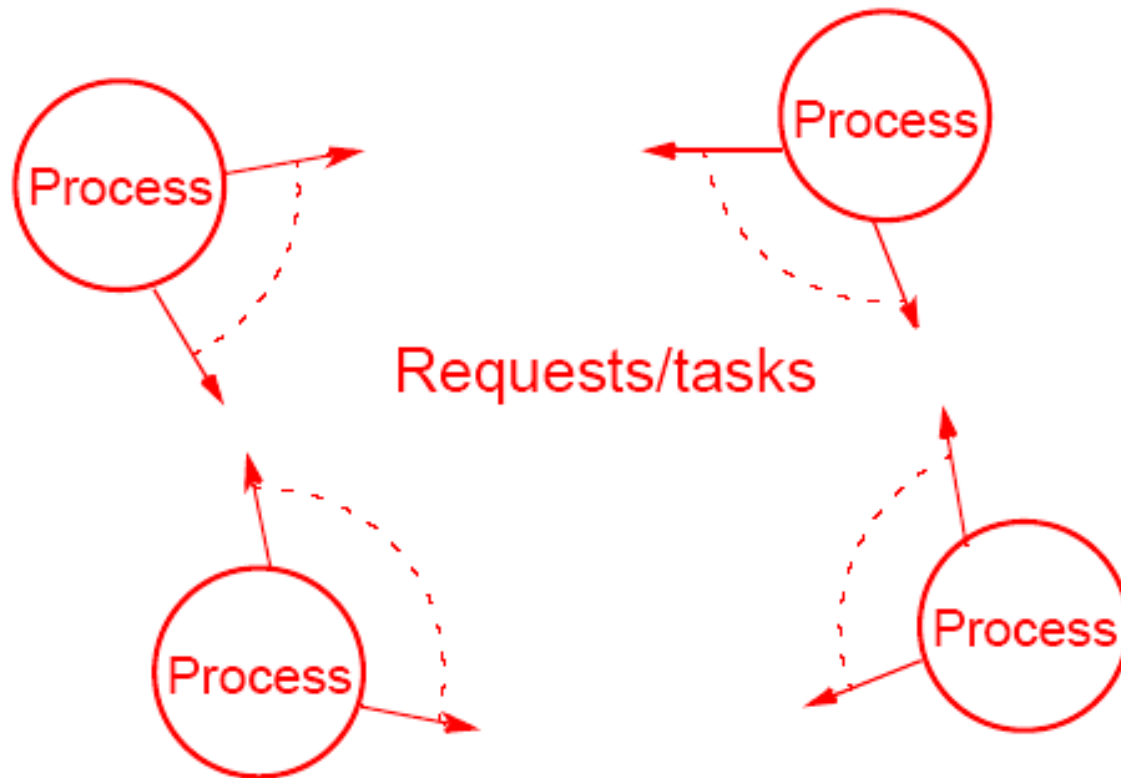

A worker process may receive tasks from other worker processes and may send tasks to other worker processes.

# Decentralized Dynamic Load Balancing Distributed Work Pool

# Fully Distributed Work Pool

Processes to execute tasks from each other

# Task Transfer Mechanisms

## Receiver-Initiated Method

A process requests tasks from other processes it selects.

Typically, a process would request tasks from other processes when it has few or no tasks to perform.

Method has been shown to work well at high system load.

Unfortunately, it can be expensive to determine process loads.

## Sender-Initiated Method

A process sends tasks to other processes it selects.

Typically, a process with a heavy load passes out some of its tasks to others that are willing to accept them.

Method has been shown to work well for light overall system loads.

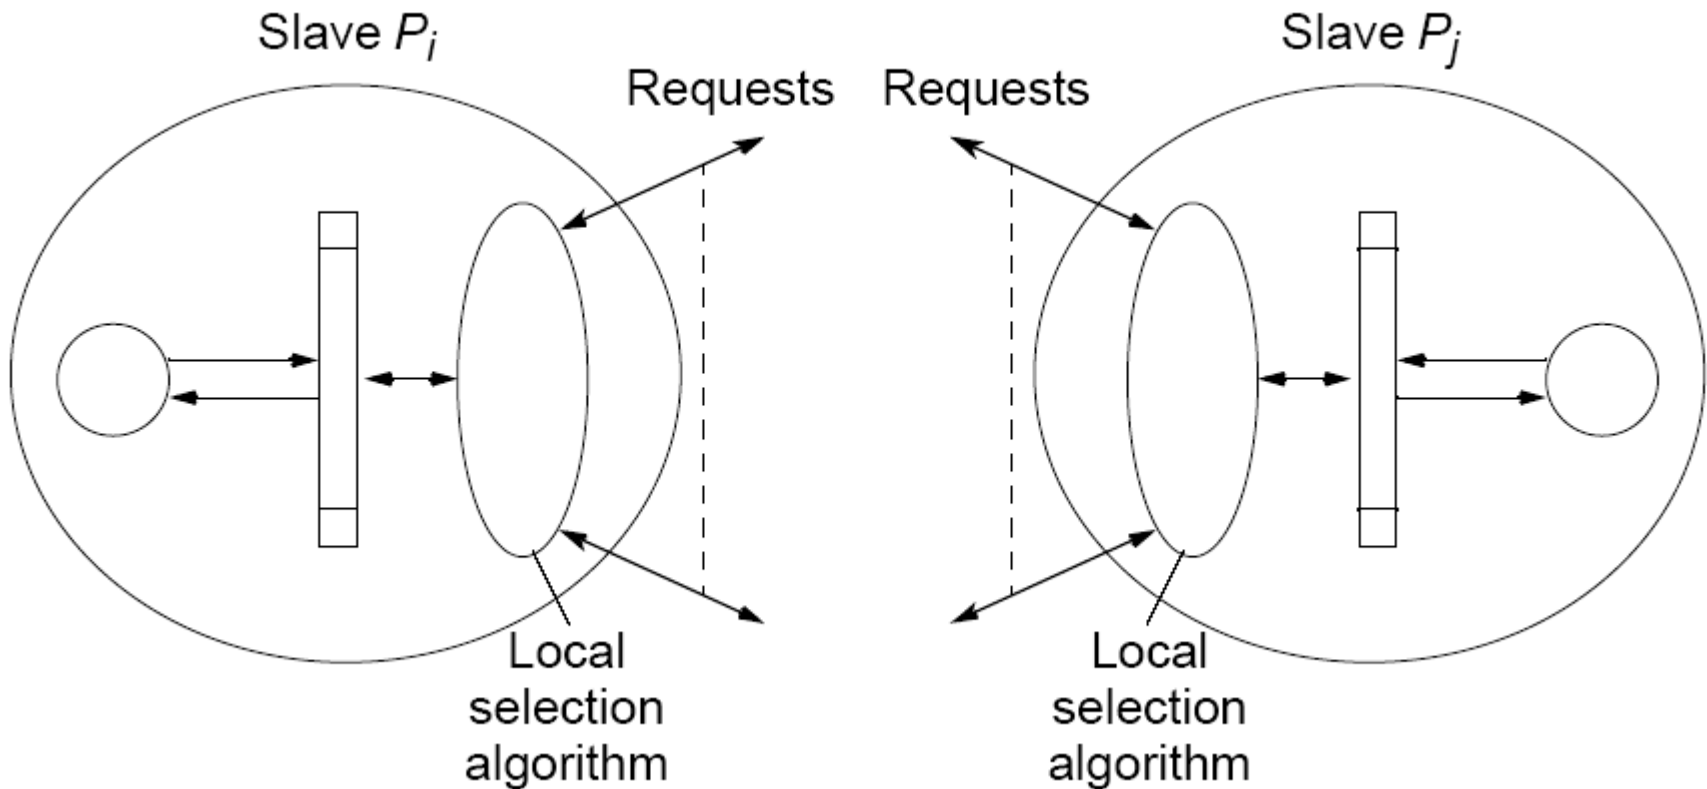

Another option is to have a mixture of methods.

Unfortunately, it can be expensive to determine process loads.

In very heavy system loads, load balancing can also be difficult to achieve because of the lack of available processes.

# Decentralized selection algorithm requesting tasks between slaves

# Process Selection

Algorithms for selecting a process:

*Round robin algorithm* – process  $P_i$  requests tasks from process  $P_x$ , where  $x$  given by a counter that is incremented after each request, using modulo  $n$  arithmetic ( $n$  processes), excluding  $x = i$ .

*Random polling algorithm* – process  $P_i$  requests tasks from process  $P_x$ , where  $x$  is a number that is selected randomly between 0 and  $n - 1$  (excluding  $i$ ).

# Round-robin scheduling

Round-robin (RR) is one of the algorithms employed by [process](#) and [network schedulers](#) in [computing](#).<sup>[1][2]</sup> As the term is generally used, [time slices](#) (also known as time quanta)<sup>[3]</sup> are assigned to each process in equal portions and in circular order, handling all processes without [priority](#) (also known as [cyclic executive](#)). Round-robin scheduling is simple, easy to implement, and [starvation-free](#). Round-robin scheduling can also be applied to other scheduling problems, such as data packet scheduling in computer networks. It is an [operating system](#) concept.

The name of the algorithm comes from the [round-robin](#) principle known from other fields, where each person takes an equal share of something in turn.

# Load Balancing Using a Line Structure

בשקף זה ובחמשת השקפים הבאים נמחיש את המנגנון איזון העומסים הדינמי עבור תצורת פייפליין

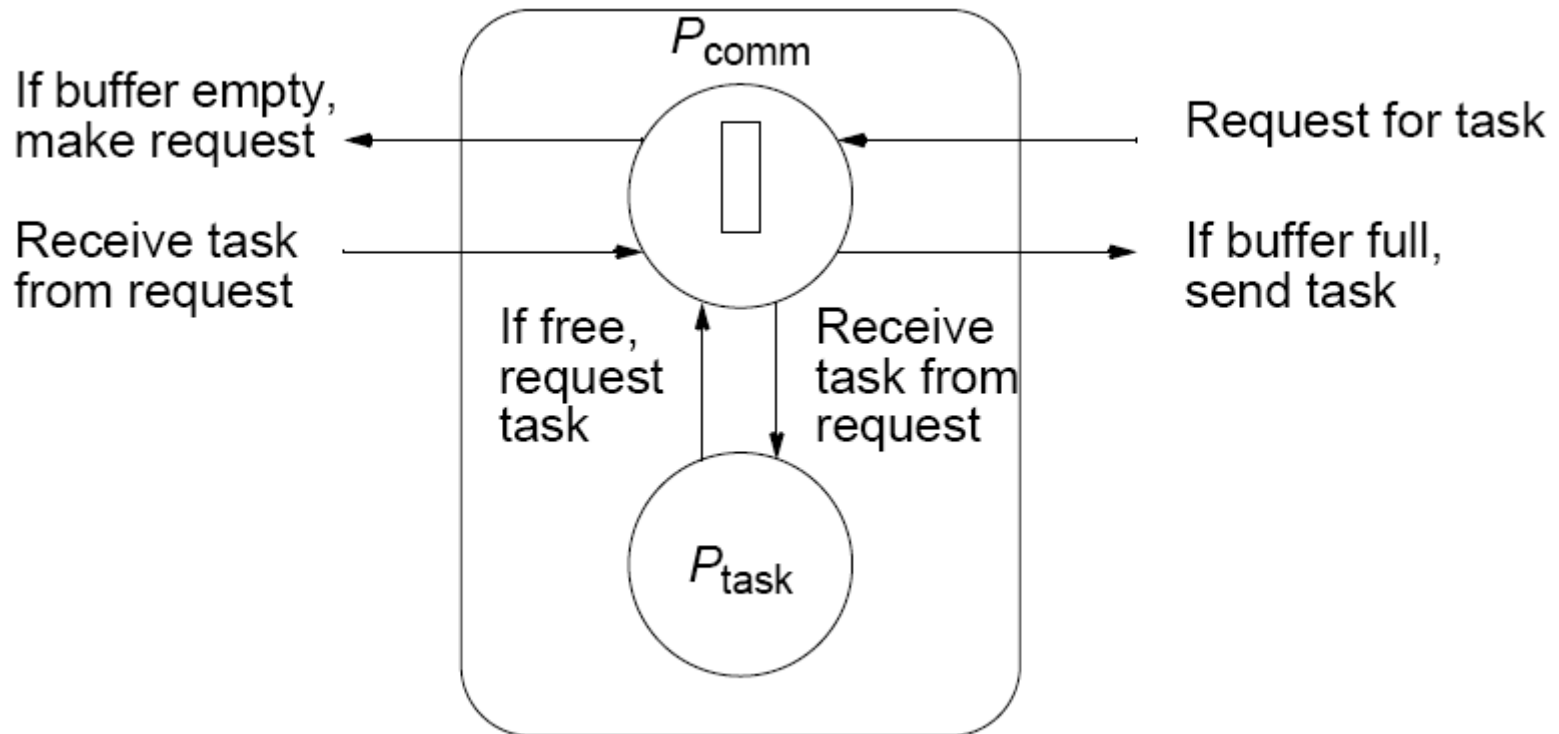

- Master process ( $P_0$ ) feeds queue with tasks at one end, and tasks are shifted down queue.
- When a process,  $P_i$  ( $1 \leq i < n$ ), detects a task at its input from queue and process is idle, it takes task from queue.
- Then tasks to left shuffle down queue so that space held by task is filled. A new task is inserted into left side end of queue.

Eventually, all processes have a task and queue filled with new tasks. High-priority or larger tasks could be placed in queue first.

# Shifting Actions

Could be orchestrated by using messages between adjacent processes:

- For left and right communication
- For the current task

# Code Using Time Sharing Between Communication and Computation

Master process ( $P_0$ )

```
for (i = 0; i < no_tasks; i++) {  
    recv(P1, request_tag);      /* request for task */  
    send(&task, Pi, task_tag); /* send tasks into queue */  
}  
recv(P1, request_tag);      /* request for task */  
send(&empty, Pi, task_tag); /* end of tasks */
```

מציין את סוף רשימת  
המשימות

## Process $P_i$ ( $1 < i < n$ )

```
if (buffer == empty) {
    send(Pi-1, request_tag);    /* request new task */
    rcv(&buffer, Pi-1, task_tag) /* task from left proc */
}
if ((buffer == full) && (!busy)) { /* get next task */
    task = buffer;                /* get task*/
    buffer = empty;              /* set buffer empty */
    busy = TRUE;                 /* set process busy */
}
nrcv(Pi+1, request_tag, request); /* check msg from right */
if (request && (buffer == full)) {
    send(&buffer, Pi+1);        /* shift task forward */
    buffer = empty;
}
if (busy) {                      /* continue on current task */
    Do some work on task.
    If task finished, set busy to false.
}
```

Nonblocking **nrcv()** necessary to check for a request being received from right.

# Nonblocking Receive Routines

## **MPI\_Irecv()**

Posts a request for message and returns immediately. Returns a request “handle”

Handle used in subsequent completion routines:

**MPI\_Wait()** -- to wait for the message

or

**MPI\_Test()** -- establish whether message has actually been received at that point.

# Termination

Computation terminates when:

- The task queue is empty and
- Every process has made a request for another task without any new tasks being generated

*Not sufficient* to terminate when task queue empty if one or more processes are still running if a running process may provide new tasks for task queue.

# Distributed Termination Detection Algorithms

## Termination Conditions

At time  $t$  requires the following conditions to be satisfied:

- Application-specific local termination conditions exist throughout the collection of processes, at time  $t$ .
- There are no messages in transit between processes at time  $t$ .

Second condition necessary because a message in transit might restart a terminated process. More difficult to recognize.

Time for messages to travel between processes not known in advance.

# A very general distributed termination algorithm

Each process in one of two states:

1. Inactive - without any task to perform
2. Active

Process that sent task to make a process enter the active state becomes its “parent.”

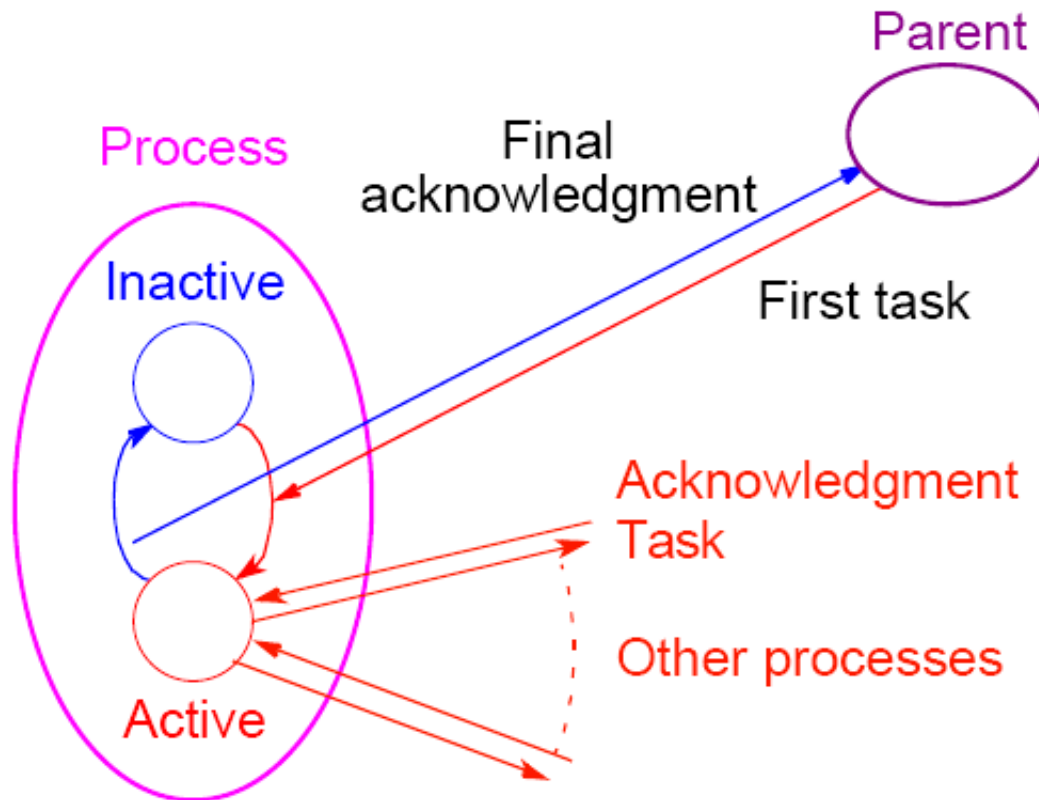

When process receives a task, it immediately sends an acknowledgment message, **except if the process it receives the task from is its parent process.**

Only sends an acknowledgment message to its parent when it is ready to become inactive, i.e. when

- Its local termination condition exists (all tasks completed), *and*
- It has transmitted all its acknowledgments for tasks it has received, *and*
- It has received all its acknowledgments for tasks it has sent out.

A process must become inactive before its parent process. When first process becomes idle, the computation can terminate.

# Termination using message acknowledgments

# Ring Termination Algorithms

## Single-pass ring termination algorithm

1. When  $P_0$  terminated, it generates token passed to  $P_1$ .
2. When  $P_i$  ( $1 \leq i < n$ ) receives token and has already terminated, it passes token onward to  $P_{i+1}$ . Otherwise, it waits for its local termination condition and then passes token onward.  $P_{n-1}$  passes token to  $P_0$ .
3. When  $P_0$  receives a token, it knows that all processes in the ring have terminated. A message can then be sent to all processes informing them of global termination, if necessary.

Algorithm assumes that a process cannot be reactivated after reaching its local termination condition. Does not apply to work pool problems in which a process can pass a new task to an idle process

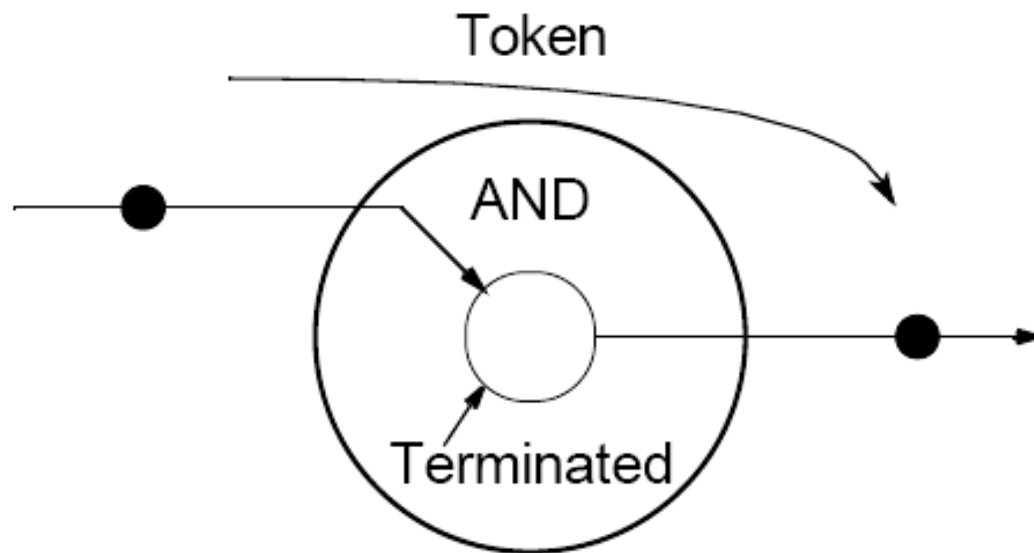

# Ring termination detection algorithm

Token passed to next processor  
when reached local termination condition

# Process algorithm for local termination

# Dual-Pass Ring Termination Algorithm

Can handle processes being reactivated but requires two passes around the ring.

Reason for reactivation is when process  $P_i$  passes a task to  $P_j$  where  $j < i$  and after a token has passed  $P_j$ . If this occurs, the token must recirculate through the ring a second time.

To differentiate circumstances, tokens colored white or black. Processes also colored white or black.

Receiving a black token means that global termination may not have occurred and token must be recirculated around ring again.

Algorithm is as follows, again starting at  $P_0$ :

1.  $P_0$  becomes white when terminated and generates white token to  $P_1$ .

2. Token passed from one process to next when each process terminated, but color of token may be changed. If  $P_i$  passes a task to  $P_j$  where  $j < i$  (before this process in the ring), it becomes a *black process*; otherwise it is a *white process*. A black process will color token black and pass it on. A white process will pass on token in its original color (either black or white). After  $P_i$  passed on a token, it becomes a white process.  $P_{n-1}$  passes token to  $P_0$ .

3. When  $P_0$  receives a black token, it passes on a white token; if it receives a white token, all processes have terminated.

In both ring algorithms,  $P_0$  becomes central point for global termination. Assumes acknowledge signal generated to each request.

# Passing task to previous processes

# MPI\_Abort

Terminates MPI execution environment

```
if (size != 2) {  
    if (rank == 0)  
        printf("Error: two processes required  
            instead of %d, abort\n", size );  
    MPI_Barrier( MPI_COMM_WORLD );  
    MPI_Abort(MPI_COMM_WORLD,  
             MPI_ERR_OTHER);  
    return -1;  
}
```

# Fixed Energy Distributed Termination Algorithm

A fixed quantity within system, colorfully termed “energy.”

- System starts with all energy being held by the root process.
- Root process passes out portions of energy with tasks to processes making requests for tasks.
- If these processes receive requests for tasks, energy divided further and passed to these processes.
- When a process becomes idle, it passes energy it holds back before requesting a new task.
- A process will not hand back its energy until all energy it handed out returned and combined to total energy held.
- When all energy returned to root and root becomes idle, all processes must be idle and computation can terminate.

# Fixed Energy Distributed Termination Algorithm

Significant disadvantage - dividing energy will be of finite precision and adding partial energies may not equate to original energy.

In addition, can only divide energy so far before it becomes essentially zero.

# Load balancing/termination detection

## Example Shortest Path Problem

Finding the shortest distance between two points on a graph.  
It can be stated as follows:

Given a set of interconnected nodes where the links between the nodes are marked with “weights,” find the path from one specific node to another specific node that has the smallest accumulated weights.

The interconnected nodes can be described by a *graph*.

The nodes are called *vertices*, and the links are called *edges*.

If the edges have implied directions (that is, an edge can only be traversed in one direction, the graph is a *directed graph*.

Graph used to find solution to many different problems; eg:

1. Shortest distance between two towns or other points on a map, where the weights represent distance
2. Quickest route to travel, where weights represent time (quickest route may not be shortest route if different modes of travel available; e.g., flying to certain towns)
3. Least expensive way to travel by air, where weights represent cost of flights between cities (the vertices)
4. Best way to climb a mountain given a terrain map with contours
5. Best route through a computer network for minimum message delay (vertices represent computers, and weights represent delay between two computers)
6. Most efficient manufacturing system, where weights represent hours of work

“The best way to climb a mountain” will be used as an example.

# Example: The Best Way to Climb a Mountain

# Graph of mountain climb

Weights in graph indicate amount of effort that would be expended in traversing the route between two connected camp sites.

The effort in one direction may be different from the effort in the opposite direction (downhill instead of uphill!). (*directed graph*)

# Graph Representation

Two basic ways that a graph can be represented in a program:

1. **Adjacency matrix** — a two-dimensional array,  $\mathbf{a}$ , in which  $\mathbf{a}[i][j]$  holds the weight associated with the edge between vertex  $i$  and vertex  $j$  if one exists
2. **Adjacency list** — for each vertex, a list of vertices directly connected to the vertex by an edge and the corresponding weights associated with the edges

Adjacency matrix used for dense graphs. Adjacency list used for sparse graphs.

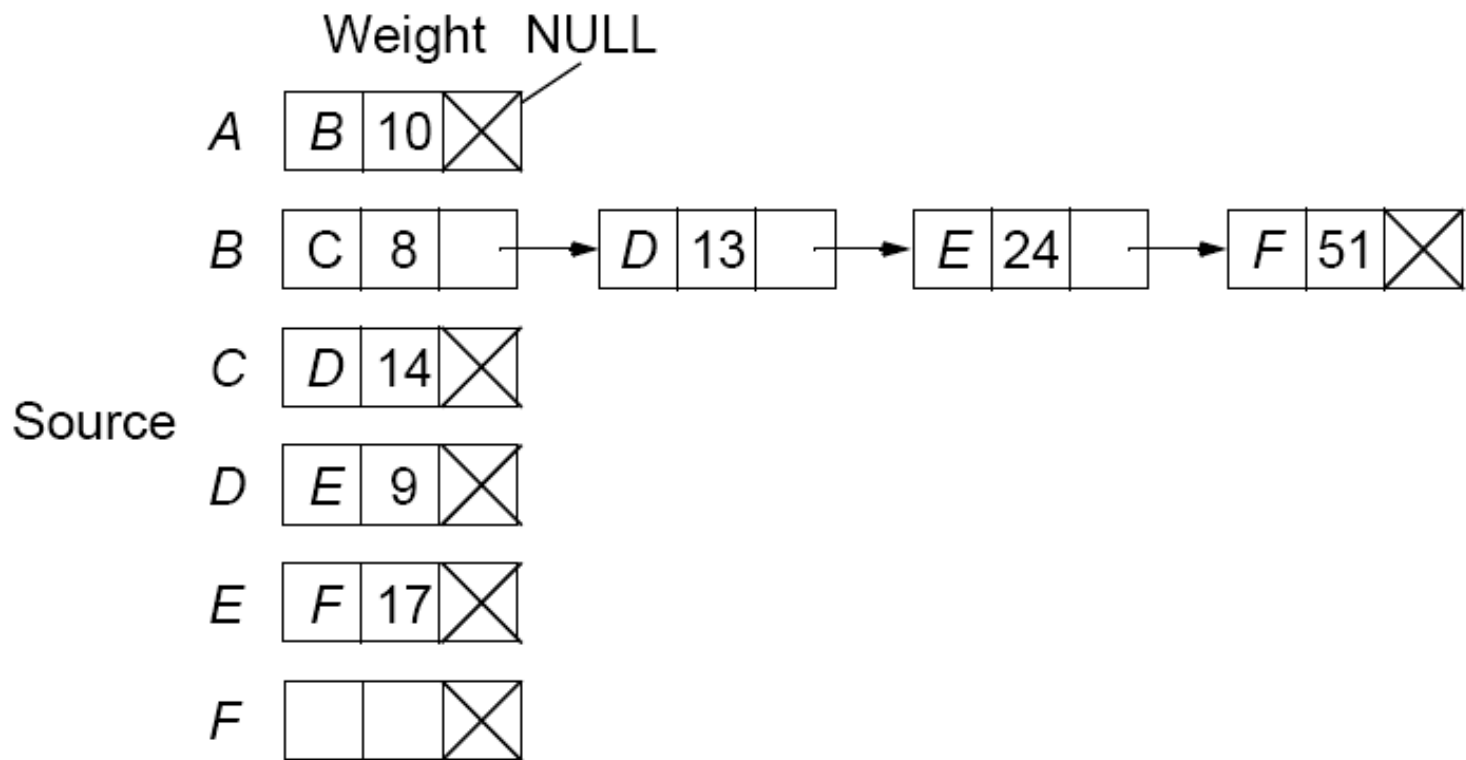

Difference based upon space (storage) requirements. Accessing the adjacency list is slower than accessing the adjacency matrix.

# Representing the graph

		Destination					
		<i>A</i>	<i>B</i>	<i>C</i>	<i>D</i>	<i>E</i>	<i>F</i>
Source	<i>A</i>	•	10	•	•	•	•
	<i>B</i>	•	•	8	13	24	51
	<i>C</i>	•	•	•	14	•	•
	<i>D</i>	•	•	•	•	9	•
	<i>E</i>	•	•	•	•	•	17
	<i>F</i>	•	•	•	•	•	•

(a) Adjacency matrix

(b) Adjacency list

# Searching a Graph

Two well-known single-source shortest-path algorithms:

- Moore's single-source shortest-path algorithm (Moore, 1957)
- Dijkstra's single-source shortest-path algorithm (Dijkstra, 1959)

which are similar.

Moore's algorithm is chosen because it is more amenable to parallel implementation although it may do more work.

The weights must all be positive values for the algorithm to work.

# Moore's Algorithm

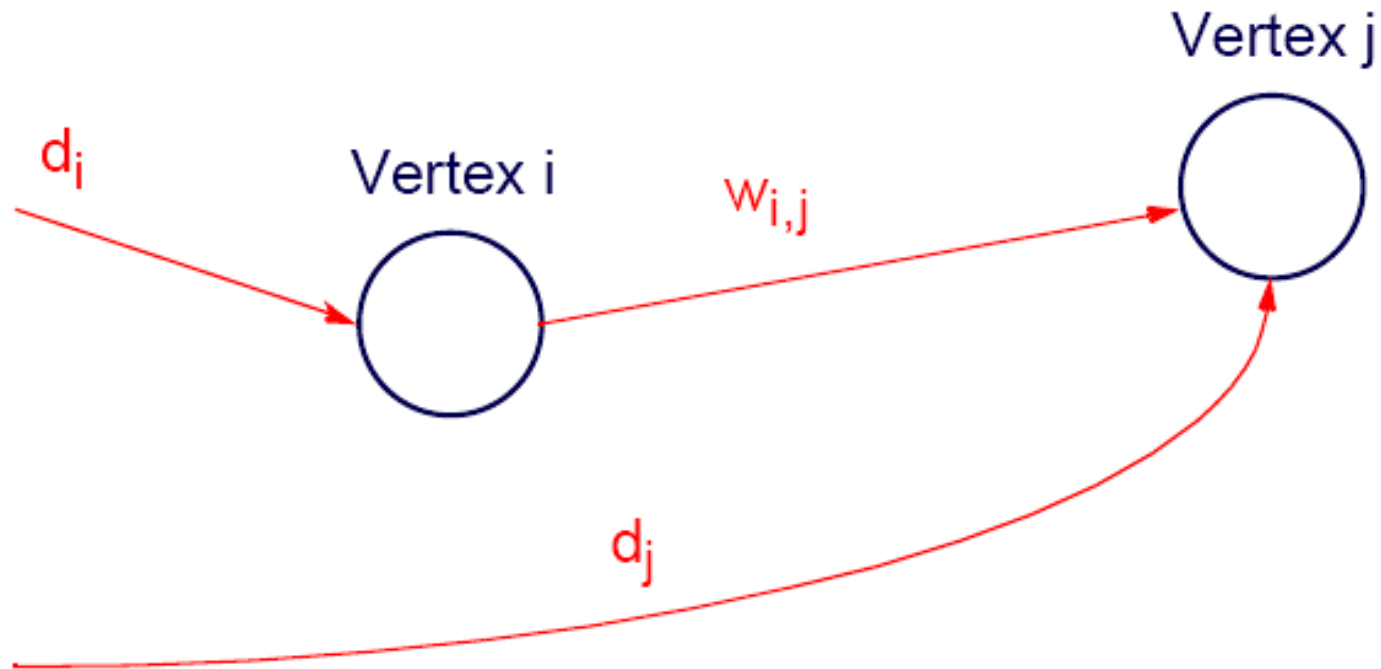

Starting with the source vertex, the basic algorithm implemented when vertex  $i$  is being considered as follows.

Find the distance to vertex  $j$  through vertex  $i$  and compare with the current minimum distance to vertex  $j$ .

Change the minimum distance if the distance through vertex  $i$  is shorter. If  $d_i$  is the current minimum distance from source vertex to vertex  $i$  and  $w_{i,j}$  is weight of edge from vertex  $i$  to vertex  $j$ :

$$d_j = \min(d_j, d_i + w_{i,j})$$

# Moore's Shortest-path Algorithm

# Data Structures

First-in-first-out vertex queue created to hold a list of vertices to examine. Initially, only source vertex is in queue.

Current shortest distance from source vertex to vertex  $i$  stored in array **dist**[ $i$ ]. At first, none of these distances known and array elements are initialized to infinity.

# Code

Suppose  $w[i][j]$  holds the weight of the edge from vertex  $i$  and vertex  $j$  (infinity if no edge). The code could be of the form

```
newdist_j = dist[i] + w[i][j];  
if (newdist_j < dist[j]) dist[j] = newdist_j;
```

When a shorter distance is found to vertex  $j$ , vertex  $j$  is added to the queue (if not already in the queue), which will cause vertex  $j$  to be examined again - **Important aspect of this algorithm, which is not present in Dijkstra's algorithm.**

# Stages in Searching a Graph

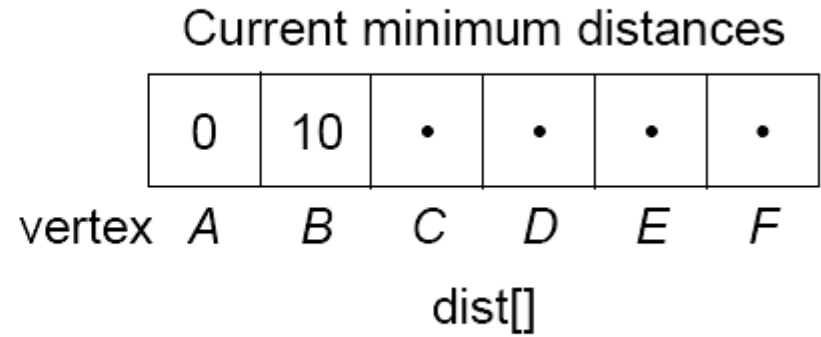

## Example

The initial values of the two key data structures are

After examining *A* to

After examining  $B$  to  $F$ ,  $E$ ,  $D$ , and  $C$ ::

Current minimum distances

0	10	18	23	34	61
---	----	----	----	----	----

vertex  $A$   $B$   $C$   $D$   $E$   $F$   
dist[]

After examining  $E$  to  $F$

Current minimum distances

0	10	18	23	34	51
---	----	----	----	----	----

vertex  $A$   $B$   $C$   $D$   $E$   $F$   
dist[]

After examining  $D$  to  $E$ :

Current minimum distances

0	10	18	23	32	51
---	----	----	----	----	----

vertex  $A$   $B$   $C$   $D$   $E$   $F$   
dist[]

After examining  $C$  to  $D$ : No changes.

After examining  $E$  (again) to  $F$  :

No more vertices to consider. Have minimum distance from vertex  $A$  to each of the other vertices, including destination vertex,  $F$ .

Usually, path required in addition to distance. Then, path stored as distances recorded. Path in our case is  $A \rightarrow B \rightarrow D \rightarrow E \rightarrow F$ .

# Sequential Code

Let `next_vertex()` return the next vertex from the vertex queue or `no_vertex` if none.

Assume that adjacency matrix used, named `w[ ][ ]`.

```
while ((i = next_vertex()) != no_vertex) /* while a vertex */
  for (j = 1; j < n; j++) /* get next edge */
    if (w[i][j] != infinity) { /* if an edge */
      newdist_j = dist[i] + w[i][j];
      if (newdist_j < dist[j]) {
        dist[j] = newdist_j;
        append_queue(j); /* add to queue if not there */
      }
    }
  /*no more to consider*/
```

# Parallel Implementations

## Centralized Work Pool

Centralized work pool holds vertex queue, `vertex_queue[]` as tasks.

Each slave takes vertices from vertex queue and returns new vertices.

Since the structure holding the graph weights is fixed, this structure could be copied into each slave, say a copied adjacency matrix.

## Master

```
while (vertex_queue() != empty) {
    recv(PANY, source = Pi);    /* request task from slave */
    v = get_vertex_queue();
    send(&v, Pi);              /* send next vertex and */
    send(&dist, &n, Pi);       /* current dist array */
    .
    recv(&j, &dist[j], PANY, source = Pi) /* new distance */
    append_queue(j, dist[j]); /* append vertex to queue */
                                /* and update distance array */
};
recv(PANY, source = Pi);    /* request task from slave */
send(Pi, termination_tag); /* termination message*/
```

## Slave (process $i$ )

```
send(Pmaster);          /* send request for task */
recv(&v, Pmaster, tag); /* get vertex number */
if (tag != termination_tag) {
    recv(&dist, &n, Pmaster); /* and dist array */
    for (j = 1; j < n; j++) /* get next edge */
        if (w[v][j] != infinity) { /* if an edge */
            newdist_j = dist[v] + w[v][j];
            if (newdist_j < dist[j]) {
                dist[j] = newdist_j;
                send(&j, &dist[j], Pmaster) /* add vertex to queue */
            }
            /* send updated distance */
        }
    }
}
```

# Decentralized Work Pool

Convenient approach is to assign slave process  $i$  to search around vertex  $i$  only and for it to have the vertex queue entry for vertex  $i$  if this exists in the queue.

The array **dist[ ]** distributed among processes so that process  $i$  maintains current minimum distance to vertex  $i$ .

Process also stores adjacency matrix/list for vertex  $i$ , for the purpose of identifying the edges from vertex  $i$ .

# Search Algorithm

Vertex  $A$  is the first vertex to search. The process assigned to vertex  $A$  is activated.

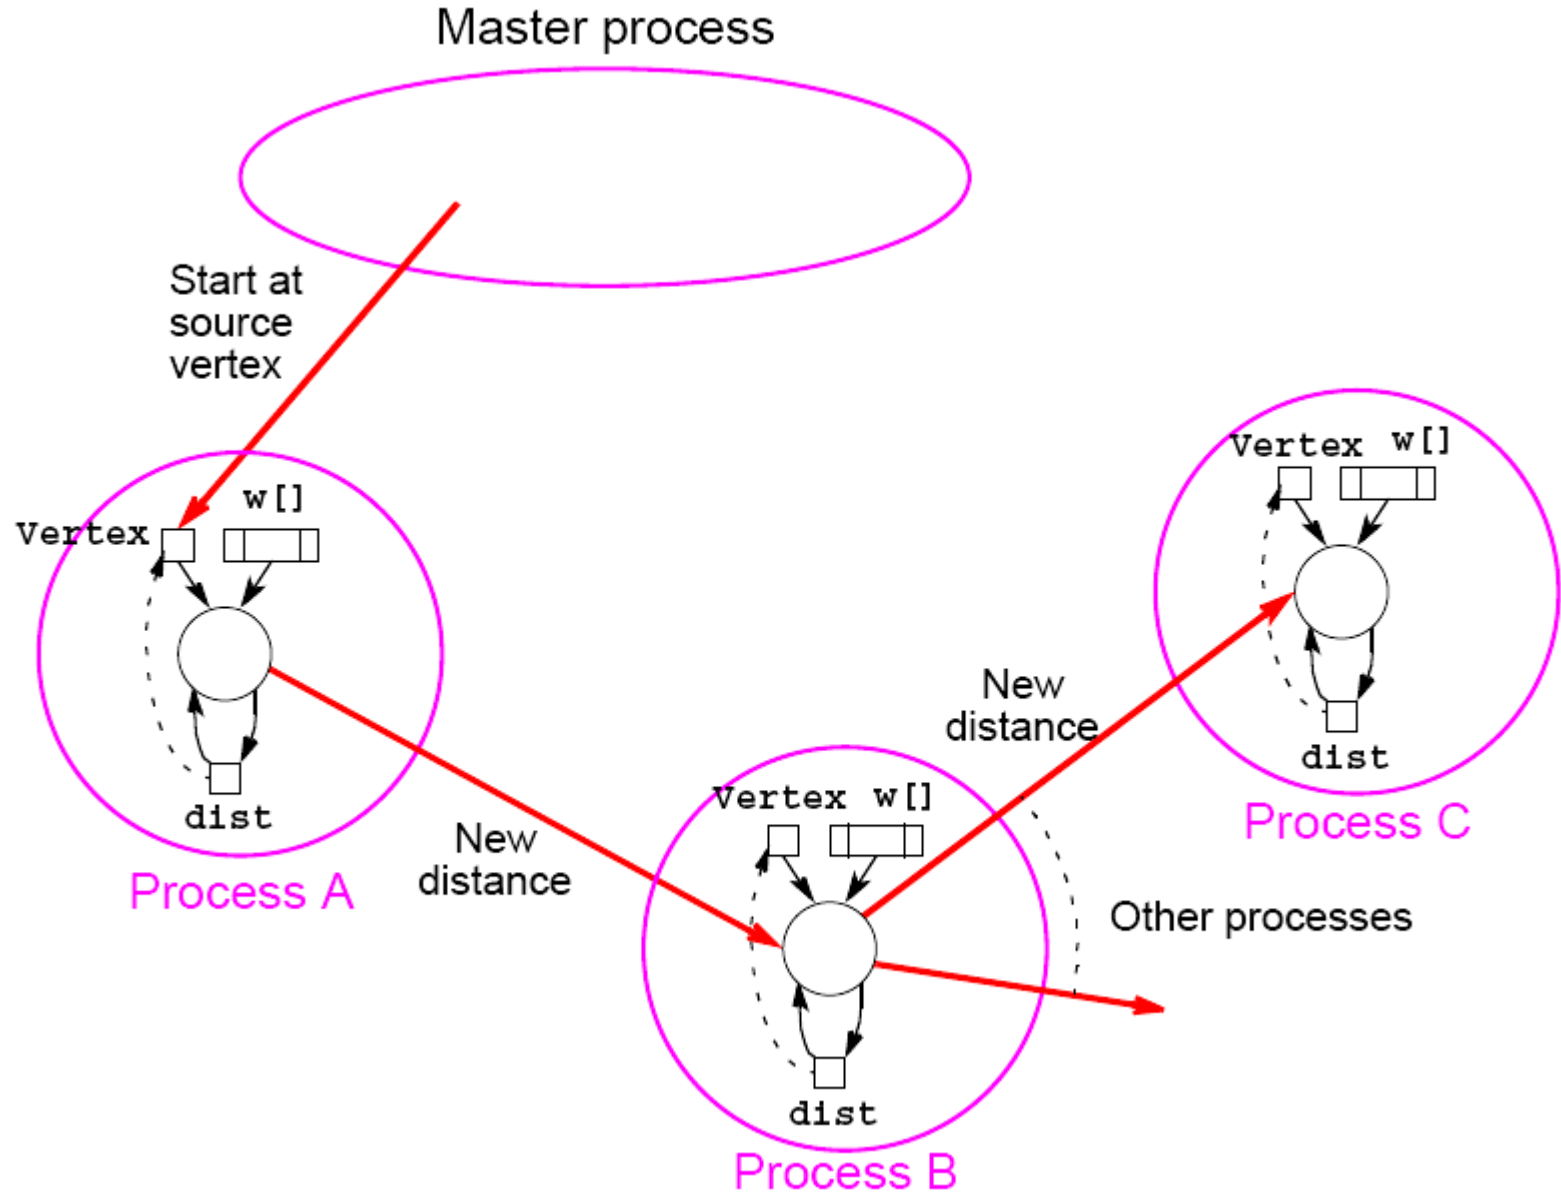

This process will search around its vertex to find distances to connected vertices.

Distance to process  $j$  will be sent to process  $j$  for it to compare with its currently stored value and replace if the currently stored value is larger.

In this fashion, all minimum distances will be updated during the search.

If the contents of  $\mathbf{d}[i]$  changes, process  $i$  will be reactivated to search again.

# Distributed graph search

Slave (process  $i$ )

```
recv(newdist, PANY);
if (newdist < dist) {
    dist = newdist;
    vertex_queue = TRUE;          /* add to queue */
} else vertex_queue == FALSE;
if (vertex_queue == TRUE) /*start searching around vertex*/
    for (j = 1; j < n; j++) /* get next edge */
        if (w[j] != infinity) {
            d = dist + w[j];
            send(&d, Pj);          /* send distance to proc j */
        }
}
```

## Simplified slave (process $i$ )

```
recv(newdist, PANY);
if (newdist < dist)
    dist = newdist;          /* start searching around vertex */
for (j = 1; j < n; j++) /* get next edge */
    if (w[j] != infinity) {
        d = dist + w[j];
        send(&d, Pj);      /* send distance to proc j */
    }
```

Mechanism necessary to repeat actions and terminate when all processes idle - must cope with messages in transit.

# Simplest solution

Use synchronous message passing, in which a process cannot proceed until destination has received message.

Process only active after its vertex is placed on queue. Possible for many processes to be inactive, leading to an inefficient solution.

Impractical for a large graph if one vertex is allocated to each processor. Group of vertices could be allocated to each processor.

# Load Balancing and Termination Detection

*Load balancing* – used to distribute computations fairly across processors in order to obtain the highest possible execution speed.

*Termination detection* – detecting when a computation has been completed. More difficult when the computation is distributed.

# Load balancing

(a) Imperfect load balancing leading to increased execution time

(b) Perfect load balancing

### Process $P_i$ ( $1 < i < n$ )

```
if (buffer == empty) {
    send(Pi-1, request_tag);    /* request new task */
    recv(&buffer, Pi-1, task_tag) /* task from left proc */
}
if ((buffer == full) && (!busy)) { /* get next task */
    task = buffer;              /* get task*/
    buffer = empty;            /* set buffer empty */
    busy = TRUE;               /* set process busy */
}
nrecv(Pi+1, request_tag, request); /* check msg from right */
if (request && (buffer == full)) {
    send(&buffer, Pi+1);        /* shift task forward */
    buffer = empty;
}
if (busy) {                    /* continue on current task */
    Do some work on task.
    If task finished, set busy to false.
}
}
```

Nonblocking **nrecv()** necessary to check for a request being received from right.

## Nonblocking Receive Routines

### **MPI\_Irecv()**

Posts a request for message and returns immediately. Returns a request “handle”

Handle used in subsequent completion routines:

**MPI\_Wait()** -- to wait for the message

or

**MPI\_Test()** -- establish whether message has actually been received at that point.

# Termination

Computation terminates when:

- The task queue is empty **and**
- Every process has made a request for another task without any new tasks being generated

*Not sufficient* to terminate when task queue empty if one or more processes are still running if a running process may provide new tasks for task queue.

## Distributed Termination Detection Algorithms

### Termination Conditions

At time  $t$  requires the following conditions to be satisfied:

- Application-specific local termination conditions exist throughout the collection of processes, at time  $t$ .
- There are no messages in transit between processes at time  $t$ .

Second condition necessary because a message in transit might restart a terminated process. More difficult to recognize.

Time for messages to travel between processes not known in advance.

## **A very general distributed termination algorithm**

Each process in one of two states:

1. Inactive - without any task to perform
2. Active

Process that sent task to make a process enter the active state becomes its “parent.”

When process receives a task, it immediately sends an acknowledgment message, **except if the process it receives the task from is its parent process.**

Only sends an acknowledgment message to its parent when it is ready to become inactive, i.e. when

- Its local termination condition exists (all tasks completed), *and*
- It has transmitted all its acknowledgments for tasks it has received, *and*
- It has received all its acknowledgments for tasks it has sent out.

A process must become inactive before its parent process. When first process becomes idle, the computation can terminate.

# Termination using message acknowledgments

## Ring Termination Algorithms

### Single-pass ring termination algorithm

1. When  $P_0$  terminated, it generates token passed to  $P_1$ .
2. When  $P_i$  ( $1 \leq i < n$ ) receives token and has already terminated, it passes token onward to  $P_{i+1}$ . Otherwise, it waits for its local termination condition and then passes token onward.  $P_{n-1}$  passes token to  $P_0$ .
3. When  $P_0$  receives a token, it knows that all processes in the ring have terminated. A message can then be sent to all processes informing them of global termination, if necessary.

Algorithm assumes that a process cannot be reactivated after reaching its local termination condition. Does not apply to work pool problems in which a process can pass a new task to an idle process

# Ring termination detection algorithm

## Process algorithm for local termination

## Dual-Pass Ring Termination Algorithm

Can handle processes being reactivated but requires two passes around the ring.

Reason for reactivation is when process  $P_i$  passes a task to  $P_j$  where  $j < i$  and after a token has passed  $P_j$ . If this occurs, the token must recirculate through the ring a second time.

To differentiate circumstances, tokens colored white or black. Processes also colored white or black.

Receiving a black token means that global termination may not have occurred and token must be recirculated around ring again.

Algorithm is as follows, again starting at  $P_0$ :

1.  $P_0$  becomes white when terminated and generates white token to  $P_1$ .

2. Token passed from one process to next when each process terminated, but color of token may be changed. If  $P_i$  passes a task to  $P_j$  where  $j < i$  (before this process in the ring), it becomes a *black process*; otherwise it is a *white process*. A black process will color token black and pass it on. A white process will pass on token in its original color (either black or white). After  $P_i$  passed on a token, it becomes a white process.  $P_{n-1}$  passes token to  $P_0$ .

3. When  $P_0$  receives a black token, it passes on a white token; if it receives a white token, all processes have terminated.

In both ring algorithms,  $P_0$  becomes central point for global termination. Assumes acknowledge signal generated to each request.

## Passing task to previous processes

# MPI\_Abort

Terminates MPI execution environment

```
if (size != 2) {  
    if (rank == 0)  
        printf("Error: two processes required  
            instead of %d, abort\n", size );  
    MPI_Barrier( MPI_COMM_WORLD );  
    MPI_Abort(MPI_COMM_WORLD,  
             MPI_ERR_OTHER);  
    return -1;  
}
```

## **Fixed Energy Distributed Termination Algorithm**

A fixed quantity within system, colorfully termed “energy.”

- System starts with all energy being held by the root process.
- Root process passes out portions of energy with tasks to processes making requests for tasks.
- If these processes receive requests for tasks, energy divided further and passed to these processes.
- When a process becomes idle, it passes energy it holds back before requesting a new task.
- A process will not hand back its energy until all energy it handed out returned and combined to total energy held.
- When all energy returned to root and root becomes idle, all processes must be idle and computation can terminate.

## **Fixed Energy Distributed Termination Algorithm**

Significant disadvantage - dividing energy will be of finite precision and adding partial energies may not equate to original energy.

In addition, can only divide energy so far before it becomes essentially zero.

## **Load balancing/termination detection**

### **Example Shortest Path Problem**

Finding the shortest distance between two points on a graph.  
It can be stated as follows:

Given a set of interconnected nodes where the links between the nodes are marked with “weights,” find the path from one specific node to another specific node that has the smallest accumulated weights.

The interconnected nodes can be described by a *graph*.

The nodes are called *vertices*, and the links are called *edges*.

If the edges have implied directions (that is, an edge can only be traversed in one direction, the graph is a *directed graph*.

Graph used to find solution to many different problems; eg:

1. Shortest distance between two towns or other points on a map, where the weights represent distance
2. Quickest route to travel, where weights represent time (quickest route may not be shortest route if different modes of travel available; e.g., flying to certain towns)
3. Least expensive way to travel by air, where weights represent cost of flights between cities (the vertices)
4. Best way to climb a mountain given a terrain map with contours
5. Best route through a computer network for minimum message delay (vertices represent computers, and weights represent delay between two computers)
6. Most efficient manufacturing system, where weights represent hours of work

**“The best way to climb a mountain” will be used as an example.**

# Example: The Best Way to Climb a Mountain

## Graph of mountain climb

Weights in graph indicate amount of effort that would be expended in traversing the route between two connected camp sites.

The effort in one direction may be different from the effort in the opposite direction (downhill instead of uphill!). (*directed graph*)

# Graph Representation

Two basic ways that a graph can be represented in a program:

1. **Adjacency matrix** — a two-dimensional array, **a**, in which **a[i][j]** holds the weight associated with the edge between vertex *i* and vertex *j* if one exists
2. **Adjacency list** — for each vertex, a list of vertices directly connected to the vertex by an edge and the corresponding weights associated with the edges

Adjacency matrix used for dense graphs. Adjacency list used for sparse graphs.

Difference based upon space (storage) requirements. Accessing the adjacency list is slower than accessing the adjacency matrix.

# Representing the graph

		Destination					
		A	B	C	D	E	F
Source	A	•	10	•	•	•	•
	B	•	•	8	13	24	51
	C	•	•	•	14	•	•
	D	•	•	•	•	9	•
	E	•	•	•	•	•	17
	F	•	•	•	•	•	•

(a) Adjacency matrix

(b) Adjacency list

# Searching a Graph

Two well-known single-source shortest-path algorithms:

- Moore's single-source shortest-path algorithm (Moore, 1957)
- Dijkstra's single-source shortest-path algorithm (Dijkstra, 1959)

which are similar.

Moore's algorithm is chosen because it is more amenable to parallel implementation although it may do more work. The weights must all be positive values for the algorithm to work.

## Moore's Algorithm

Starting with the source vertex, the basic algorithm implemented when vertex  $i$  is being considered as follows.

Find the distance to vertex  $j$  through vertex  $i$  and compare with the current minimum distance to vertex  $j$ .

Change the minimum distance if the distance through vertex  $i$  is shorter. If  $d_i$  is the current minimum distance from source vertex to vertex  $i$  and  $w_{i,j}$  is weight of edge from vertex  $i$  to vertex  $j$ :

$$d_j = \min(d_j, d_i + w_{i,j})$$

## Moore's Shortest-path Algorithm

## Data Structures

First-in-first-out vertex queue created to hold a list of vertices to examine. Initially, only source vertex is in queue.

Current shortest distance from source vertex to vertex  $i$  stored in array **dist[i]**. At first, none of these distances known and array elements are initialized to infinity.

## Code

Suppose  $w[i][j]$  holds the weight of the edge from vertex  $i$  and vertex  $j$  (infinity if no edge). The code could be of the form

```
newdist_j = dist[i] + w[i][j];  
if (newdist_j < dist[j]) dist[j] = newdist_j;
```

When a shorter distance is found to vertex  $j$ , vertex  $j$  is added to the queue (if not already in the queue), which will cause vertex  $j$  to be examined again - **Important aspect of this algorithm, which is not present in Dijkstra's algorithm.**

# Stages in Searching a Graph

## Example

The initial values of the two key data structures are

Vertices to consider

A					
---	--	--	--	--	--

vertex\_queue

Current minimum distances

0	.	.	.	.	.
---	---	---	---	---	---

vertex A B C D E F

dist[]

After examining *A* to

After examining *B* to *F*, *E*, *D*, and *C*::

Current minimum distances

0	10	18	23	34	61
---	----	----	----	----	----

vertex *A* *B* *C* *D* *E* *F*  
dist[]

After examining *E* to *F*

Current minimum distances

0	10	18	23	34	51
---	----	----	----	----	----

vertex *A* *B* *C* *D* *E* *F*  
dist[]

After examining *D* to *E*:

Current minimum distances

0	10	18	23	32	51
---	----	----	----	----	----

vertex A B C D E F  
dist[]

After examining *C* to *D*: No changes.  
After examining *E* (again) to *F* :

Vertices to consider						Current minimum distances						
						0	10	18	23	32	49	
vertex_queue						vertex	<i>A</i>	<i>B</i>	<i>C</i>	<i>D</i>	<i>E</i>	<i>F</i>
						dist[]						

No more vertices to consider. Have minimum distance from vertex *A* to each of the other vertices, including destination vertex, *F*.

Usually, path required in addition to distance. Then, path stored as distances recorded. Path in our case is *A* -> *B* -> *D* -> *E* -> *F*.

## Sequential Code

Let `next_vertex()` return the next vertex from the vertex queue or `no_vertex` if none.

Assume that adjacency matrix used, named `w[ ][ ]`.

```
while ((i = next_vertex()) != no_vertex) /* while a vertex */
  for (j = 1; j < n; j++)                /* get next edge */
    if (w[i][j] != infinity) {           /* if an edge */
      newdist_j = dist[i] + w[i][j];
      if (newdist_j < dist[j]) {
        dist[j] = newdist_j;
        append_queue(j);                 /* add to queue if not there */
      }
    }
}
```

# Parallel Implementations

## Centralized Work Pool

Centralized work pool holds vertex queue, `vertex_queue[]` as tasks.

Each slave takes vertices from vertex queue and returns new vertices.

Since the structure holding the graph weights is fixed, this structure could be copied into each slave, say a copied adjacency matrix.

## Master

```
while (vertex_queue() != empty) {
    recv(PANY, source = Pi); /* request task from slave */
    v = get_vertex_queue();
    send(&v, Pi);           /* send next vertex and */
    send(&dist, &n, Pi);    /* current dist array */

    .
    recv(&j, &dist[j], PANY, source = Pi)/* new distance */
    append_queue(j, dist[j]); /* append vertex to queue */
                                /* and update distance array */
};
recv(PANY, source = Pi); /* request task from slave */
send(Pi, termination_tag); /* termination message*/
```

## Slave (process *i*)

```
send(Pmaster);          /* send request for task */
recv(&v, Pmaster, tag); /* get vertex number */
if (tag != termination_tag) {
    recv(&dist, &n, Pmaster); /* and dist array */
    for (j = 1; j < n; j++) /* get next edge */
        if (w[v][j] != infinity) { /* if an edge */
            newdist_j = dist[v] + w[v][j];
            if (newdist_j < dist[j]) {
                dist[j] = newdist_j;
                send(&j, &dist[j], Pmaster) /* add vertex to queue */
            }
            /* send updated distance */
        }
    }
}
```

## Decentralized Work Pool

Convenient approach is to assign slave process  $i$  to search around vertex  $i$  only and for it to have the vertex queue entry for vertex  $i$  if this exists in the queue.

The array `dist[ ]` distributed among processes so that process  $i$  maintains current minimum distance to vertex  $i$ .

Process also stores adjacency matrix/list for vertex  $i$ , for the purpose of identifying the edges from vertex  $i$ .

## Search Algorithm

Vertex  $A$  is the first vertex to search. The process assigned to vertex  $A$  is activated.

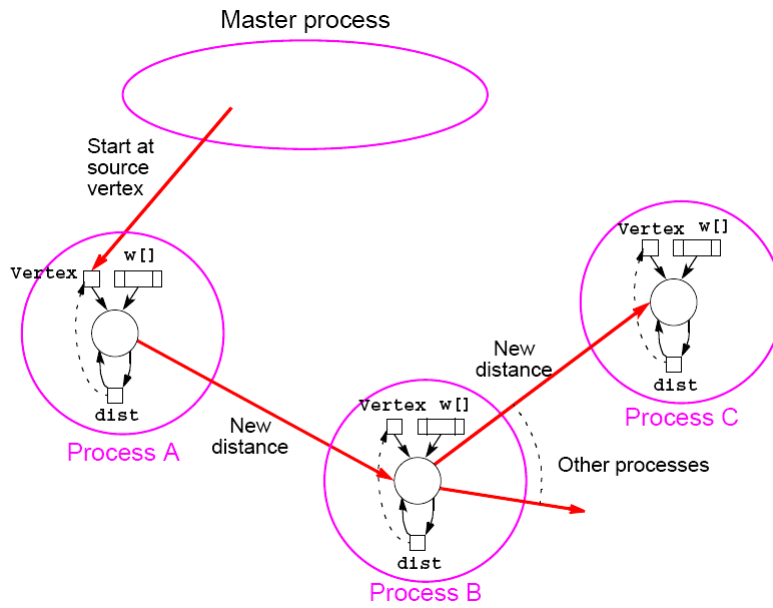

This process will search around its vertex to find distances to connected vertices.

Distance to process  $j$  will be sent to process  $j$  for it to compare with its currently stored value and replace if the currently stored value is larger.

In this fashion, all minimum distances will be updated during the search.

If the contents of  $d[i]$  changes, process  $i$  will be reactivated to search again.

# Distributed graph search

Slave (process  $i$ )

```
recv(newdist, PANY);
if (newdist < dist) {
    dist = newdist;
    vertex_queue = TRUE;      /* add to queue */
} else vertex_queue == FALSE;
if (vertex_queue == TRUE) /*start searching around vertex*/
    for (j = 1; j < n; j++) /* get next edge */
        if (w[j] != infinity) {
            d = dist + w[j];
            send(&d, Pj);      /* send distance to proc j */
        }
}
```

## Simplified slave (process $i$ )

```
recv(newdist, PANY);
if (newdist < dist)
    dist = newdist;          /* start searching around vertex */
for (j = 1; j < n; j++) /* get next edge */
    if (w[j] != infinity) {
        d = dist + w[j];
        send(&d, Pj);      /* send distance to proc j */
    }
```

Mechanism necessary to repeat actions and terminate when all processes idle - must cope with messages in transit.

## **Simplest solution**

Use synchronous message passing, in which a process cannot proceed until destination has received message.

Process only active after its vertex is placed on queue. Possible for many processes to be inactive, leading to an inefficient solution.

Impractical for a large graph if one vertex is allocated to each processor. Group of vertices could be allocated to each processor.
